Density functional calculations have been employed to rationalize why the heteronuclear N₂-bridged Mo₃⁺Nb(III) dimer, [Ar(Bu)N]₃Mo(N-Pr)Ar, (Ar = 3,5-C₆H₃Me₂), does not undergo cleavage of the dinitrogen bridge in contrast to the analogous Mo₃⁺Mo(III) complex which, although having a less activated N-N bond, undergoes spontaneous dinitrogen cleavage at room temperature. The calculations reveal that although the overall reaction is exothermic for both systems, the actual cleavage step is endothermic by 144 kJ mol⁻¹ for the Mo₃⁺Nb(III) complex whereas the Mo₃⁺Mo(III) system is exothermic by 94 kJ mol⁻¹. The reluctance of the Mo₃⁺Nb(III) system to undergo N₂ cleavage is attributed to its d^0 metal configuration which is one electron short of the d^2 configuration necessary to reductively cleave the dinitrogen bridge.

This is confirmed by additional calculations on the related d^2 Mo₃⁺Nb and Nb²⁺N₃ systems for which the cleavage step is calculated to be substantially exothermic, accounting for why in the presence of the reductant KC₃, the [Ar(Bu)N]₃Mo-(µ-N₂)Nb(N-Pr)Ar, complex was observed to undergo spontaneous cleavage of the dinitrogen bridge. On the basis of these results, it can be concluded that the level of activation of the N–N bond does not necessarily correlate with the ease of cleavage of the dinitrogen bridge.

Introduction
Despite the overall favourable thermodynamics, development of an energy-efficient process for nitrogen fixation continues to present a significant chemical challenge, namely due to the high kinetic barrier to breaking the extremely strong N≡N triple bond. Given the crucial role played by transition metal ions in maintaining the enzyme nitrogenase, numerous efforts have been made synthetically to develop transition metal based catalysts that activate dinitrogen under similar conditions.

A recent discovery of interest in the activation of dinitrogen is the reaction involving the coordinatively unsaturated, three-coordinate Mo(III) complex developed by Laplaza and Cummins. In this reaction, the sterically-hindered, three-coordinate molybdenum(III) complex Mo[O(N)]Ar₂, (R = C(CH₃)₂CH₂Ar, Ar = 3,5-C₆H₃Me₂) spontaneously reacts with dinitrogen resulting in its cleavage at room temperature to form the nitrido product [Ar(R)N]MoN. The cleavage reaction proceeds via the dimeric intermediate [Ar(R)N]Mo(µ-N₂)Mo(N[R]Ar), which, on the basis of magnetic measurements on the related [Ph(Bu)N]₃Mo(µ-N₂)Mo[N(Bu)Ph] complex, is assumed to possess a spin triplet ground state.

The intermediate dimer can be isolated at lower temperatures and its structural characterization by extended X-ray absorption fine structure (EXAFS) has revealed a linear Mo–N–Mo core containing an end-on dinitrogen bridge unit with a N–N bond length of 1.19(2) Å (cf. 1.10 Å in free N₂), and an approximately trigonal arrangement of the bulky (R)NAr amide groups.

More recently, the related heteronuclear Mo₃⁺Nb(III) dinitrogen-bridged dimer [Ar(Bu)N]₃Mo(µ-N₂)Nb(N-Pr)Ar, has been isolated and structurally characterized by single-crystal X-ray diffraction. The ground state of the complex is a spin doublet and surprisingly, although the dinitrogen bridge is significantly more activated (N–N distance of 1.235(10) Å) than in the above dimolybdenum(III) intermediate, the complex does not undergo N₂ cleavage. However, in the presence of the reductant KC₃, the dinitrogen bridge is cleaved resulting in the formation of the nitrido products [Ar(Bu)N]₃MoN and [Ar(Pr)N]₃NbN.

The X-ray structure of the [Ar(Bu)N]₃Mo(µ-N₂)Nb(N-Pr)Ar dimer reveals significant deviation from the trigonal structure found for the related dimolybdenum intermediate. The [Ar(Pr)N] ligands do not have the expected trigonal arrangement around the Nb center and instead have undergone significant rotation about the Nb–N(amide) axes. Furthermore, the Mo–N–N–Mo core is not linear but bent by approximately 13° at the Nb end. The rotated ligand structure is of interest as our previous DFT study of the model dimolybdenum(III) system (NH₃)₂Mo(µ-N₂)Mo(NH₃) showed that a 90° rotation of one of the amide ligands on each Mo center resulted in a 60 kJ mol⁻¹ stabilization of the spin singlet structure making it the preferred ground state over the spin triplet structure which adopts a trigonal arrangement of the NH₃ ligands.

In this study, we have used DFT methods to calculate and compare the structures and energetics of the heteronuclear Mo₃⁺Nb(III) and Mo₃⁺N₃ systems with those of the analogous dimolybdenum(III) and dinobium(II) complexes in order to rationalise the differing reactivities of the above experimentally known Mo₃⁺Mo(III) and Mo₃⁺N₃ systems towards cleavage of the dinitrogen bridge.

Computational details
The calculations carried out in this work were performed using the Amsterdam Density Functional (ADF)¹⁻¹⁰ program (version 2002.03) running on either Linux-based Pentium IV computers or the Australian National University Supercomputing Facility.

All calculations employed the local density approximation (LDA) to the exchange potential, the correlation potential of Vosko, Wilk and Nusair (VWN),¹¹ the Becke¹² and Perdew¹³ corrections for non-local exchange and correlation, and the numerical integration scheme of te Velde and coworkers.¹⁴ Geometry optimisations were performed using the gradient algorithm of Versluis and Ziegler.¹⁵ All electron, triple-ζ Slater type orbital basis sets with polarization functions (TZP) were used for all atoms. Relativistic effects were incorporated using the zero order relativistic approximation (ZORA)¹⁶⁻¹⁸ functionality in ADF. Frequencies were computed in ADF by numerical differentiation of energy gradients in slightly displaced geometries to confirm that optimized structures were true minima. All calculations were carried out in a spin-unrestricted manner.

Results and discussion
Analogous to our previous study on the Mo₃⁺Mo(III) system, the calculations employed model complexes where the bulky [Ar(Bu)N] and [N(Pr)N] groups were replaced with simple amide ligands NH₂. For all three systems, Mo₃⁺Mo(III), Mo₃⁺N₃ and Nb²⁺N₃, geometry optimizations were completed for four of the five species along the reaction path shown schematically in Fig. 1, including the reactants, M(NH₃)₂ and M'(NH₃)₃, encounter complexes, M–N–M'(NH₃)₂ and...

*Ligands are approximately trigonal.*

Fig. 1 Proposed reaction sequence associated with N$_2$ cleavage by the Laplaza and Cummins three-coordinate complex Mo[N(R)Ar]$_3$.

N$_2$·M$^I$·(NH$_3$)$_3$; intermediate dimer, (NH$_3$)$_3$·M$^I$·N=N·M$^I$·(NH$_3$)$_3$; and products (NH$_3$)$_3$·M$^I$·N and (NH$_3$)$_3$·M$^I$·N, and compared with our earlier calculations on the Mo$^{III}$Mo$^{III}$ system.

The relative energies of the species along the reaction pathway for the Mo$^{III}$Nb$^{III}$ system are shown in Fig. 2. The first step in the lowest energy pathway is the binding of $N_2$ to Nb$^{III}$·(NH$_3$)$_3$, with a triplet ground state, to form the encounter complex N$_2$·Nb$^{III}$·(NH$_3$)$_3$ also in the triplet spin state. Unlike the Mo$^{III}$Mo$^{III}$ system, spin crossover is not required to form the encounter complex. Mo$^{III}$·(NH$_3$)$_3$ then binds to the encounter complex to form the intermediate dimer (NH$_3$)$_3$·Nb$^{III}$·N=N·Mo·(NH$_3$)$_3$ with a doublet ground state. Unlike the Mo$^{III}$Mo$^{III}$ system where the singlet and triplet spin states of the intermediate dimer are relatively close in energy, the quartet spin state for the Mo$^{III}$Nb$^{III}$ dimer is calculated to lie 132 kJ mol$^{-1}$ higher in energy.

Fig. 2 Calculated energies of the species involved in the N$_2$ cleavage reaction relative to the reactants for the Mo$^{III}$Nb$^{III}$ system.

Experimentally the intermediate dimer is formed by the reaction of NbCl(N(Pr)Ar), with a [(N$_2$)Mo(N(Pr)Ar)]$^+$ salt; however, calculations on the encounter complex (NH$_3$)$_3$·M$^I$·N=N reveal that in the case of the heteronuclear Mo$^{III}$Nb$^{III}$ and Mo$^{III}$Nb$^I$ systems, it is energetically more favorable by approximately 8 kJ mol$^{-1}$ and 56 kJ mol$^{-1}$, respectively, for the dinitrogen to bind first to the (NH$_3$)$_3$Nb$^{III}$ (S = 1) or (NH$_3$)$_3$Nb$^I$ (S = 3/2) reactant rather than (NH$_3$)$_3$Mo$^{III}$. This result can be attributed to the greater radial extent of the valence $d$ orbitals of Nb$^{III}$ and Nb$^I$ relative to Mo$^{III}$ and therefore a larger propensity for metal–dinitrogen backbonding.

The calculated energies for the reactants, intermediate dimer and products for the Mo$^{III}$Mo$^{III}$, Mo$^{III}$Nb$^{III}$, Mo$^{III}$Nb$^I$, and Nb$^{III}$Nb$^I$ systems are given in Table 1 along with the ground spin state and N–N bond length for the intermediate dimer, and the overall stabilization energy of the products relative to the reactants. The computed activation energies associated with the cleavage of the dinitrogen bridge to form the nitrido products, are also tabulated, and are based on linear transit calculations on the intermediate dimer where the N–N bond length was progressively incremented in steps of 0.05 Å with all other geometrical parameters being allowed to optimize. The energies of the intermediate dimer and products for each system are plotted relative to the reactants in Fig. 3.

Fig. 3 Calculated energies of the intermediate dimers and products relative to the reactants for the Mo$^{III}$Mo$^{III}$, Mo$^{III}$Nb$^{III}$, Mo$^{III}$Nb$^I$, and Nb$^{III}$Nb$^I$ systems.

The reactants adopt $D_{3h}$ symmetry and the products $C_{3v}$ symmetry for Mo$^{III}$ and Nb$^I$ whereas for Nb$^{III}$, both the reactants and products have $C_s$ symmetry. The encounter complexes for all four systems have approximately $C_s$ symmetry with one ligand rotated by $90^\circ$.

The lowest energy structure for the intermediate dimer (see Fig. 4) possessed $C_{3v}$ symmetry for the Mo$^{III}$Mo$^{III}$ and Nb$^{III}$Nb$^I$ systems but $C_s$ symmetry for Mo$^{III}$Nb$^{III}$ and Mo$^{III}$Nb$^I$. In all dimer structures except Nb$^{III}$Nb$^I$, rotation of the NH$_3$ ligands away from a trigonal arrangement was observed on both metal centers. The Mo$^{III}$Nb$^{III}$ dimer was calculated to have a spin doublet ground state, in agreement with experiment, while the Mo$^{III}$Nb$^I$ and Mo$^{III}$Nb$^{III}$ systems are predicted to have spin singlet ground states. The Nb$^{III}$Nb$^I$ dimer is calculated to have a spin triplet ground state but with the singlet lying only 7 kJ mol$^{-1}$ higher in energy. The quartet and doublet spin states of the Nb$^I$(NH$_3$)$_3$ reactant also lie very close in energy unlike Mo$^{III}$·(NH$_3$)$_3$, where they are separated by 59 kJ mol$^{-1}$.

Fig. 4 Optimized structures for the Mo$^{III}$Mo$^{III}$, Mo$^{III}$Nb$^{III}$, Mo$^{III}$Nb$^I$, and Nb$^{III}$Nb$^I$ intermediate dimers in their ground state.
The level of dinitrogen activation, as measured by the N–N bond length which varies between 1.22 and 1.28 Å, is smallest for the MoIIIMoIII system and greatest for the NbIIIIB system. The calculated N–N bond length of 1.237 Å for the MoIIINbIII complex is very close to the experimental value of 1.235 Å. The larger N2 activation for the NbIIIIB complex is consistent with our earlier work on other dinitrogen-bridged d4 dimers which revealed that for isoelectronic metals in any one transition series, the degree of N2 activation increases towards the LHS of the period due to the increased size of the valence d orbitals and thus the capacity of the metal to back donate into the dinitrogen π* orbitals.

The overall cleavage reaction is found to be exothermic for all four systems (see Fig. 3) but the stabilization energy for the MoIIIMoIII system is significantly lower by at least 175 kJ mol⁻¹, even though the N–N bond is more activated than in the MoIIIMoII system. More importantly, whereas the N2 cleavage step for the MoIIIMoIII, NbIIIB and MoIIINbIIIB systems is exothermic, with the barriers to bond cleavage (calculated activation energies, Ea, between 50 and 70 kJ mol⁻¹) all accessible at room temperature, the corresponding step in the MoIIINbIII system is endothermic by 144 kJ mol⁻¹. The dependence of the total energy on the N–N bond length is plotted in Fig. 5 for the MoIIINbIIIB and MoIIINbIIIB dimers. For MoIIINbIII, the N2 cleavage step is favourable in the singlet spin state with a barrier of 70 kJ mol⁻¹. Analogous to the MoIIIMoII and MoIIINbIIIB systems, the triplet and singlet spin states are relatively close for the dimer but N2 cleavage is endothermic in the triplet spin state. However, for the MoIIINbIII system, the reverse cleavage reaction, from products to intermediate dimer, is barrierless in the doublet spin state. N2 cleavage is even less favourable in the quartet state as the products are destabilized relative to the reactants.

The endothermicity of the N2 cleavage step for MoIIINbIII accounts for the observed resistance of the MoIIINbIII dimer to cleavage of the bridging dinitrogen in the absence of a reducing agent. This is in agreement with our earlier calculations on the analogous TaIIITaIII dimer which showed that although the complex has a very activated N–N bond of 1.277 Å, the N2 bond cleavage step is endothermic by nearly 460 kJ mol⁻¹. On the basis of these results, it can be concluded that the level of activation of the N–N bond does not necessarily correlate with the ease of cleavage of the dinitrogen bridge.

Our previous study compared the level of N2 activation and energetics associated with the N2 cleavage reaction for the third row metals TaIIITaIII and ReIIIT which possess d4, d5 and d6 configurations, respectively. The results of that study showed that the cleavage reaction was most favored for d4 metals as this configuration provides the six electrons necessary to reduce the dinitrogen to form the nitrido products. Calculations in the current study on the d5 MoIIINbIII and NbIIINbIII intermediate dimers were found to be consistent with this finding in that, unlike the d4 configuration of the MoIIINbIII dimer, the reaction step involving cleavage of the dinitrogen bridge to form the nitrido products was exothermic in both cases by 45 and 401 kJ mol⁻¹, respectively (see Table 1 and Fig. 2). Furthermore, the calculated N–N bond lengths of 1.270 and 1.279 Å are more activated than the value of 1.221 Å predicted for the MoIIIMoIII. The exothermic cleavage step for the MoIIINbIII dimer accounts for why the MoIIINbIII complex, in the presence of the reducing KC₇₇, results in the cleavage of the dinitrogen bridge as the reduction step is most likely metal-centred with NbIII being reduced to NbII.

Although the MoIIINbIII and the TaIIITaIII systems have unfavourable thermodynamics in relation to the cleavage of dinitrogen, the fact that, in principle, these systems can be isolated with significantly activated N2 bonds is useful when controlled reactivities of the dinitrogen bridge are desired such as protonation reactions to form ammonia and hydrazine.

In the current study, model systems have been employed where the bulky N(R)Ar amide ligands have been replaced with NH₂. However, both the structures and reaction energetics will be influenced by the steric bulk of the N(R)Ar groups and we intend to investigate these effects in the MoIIIMoIII and MoIIINbIII systems in a forthcoming paper using DFT based QM/MM methods.

**Conclusion**

DFT calculations have shown the importance of the metal d⁴ configuration in effecting cleavage of the dinitrogen bridge in [Ar(RN)₂M(μ-N₂)Ar] complexes. Experimentally, the heteronuclear d⁴ MoIIINbIII dimer [Ar(BuN)₂M(μ-N₂)N₂Pr] (Ar = 3,5-C₅H₅Me₂) does not undergo cleavage of the dinitrogen bridge, consistent with the theoretical calculations on the model complexes (NH₂)₂M(μ-N₂)Nb(NH₂), which reveal that the cleavage step is significantly endothermic by 144 kJ mol⁻¹. In contrast, although the analogous MoIIIMoIII dimer [Ar(BuN)₂M(μ-N₂)Mo(N(Bu)Ar)] possesses a less activated N2 bridge, this system is observed to undergo spontaneous cleavage at room temperature. The markedly differing reactivities of these two systems can be accounted for on the basis that the MoIIINbIII dimer is one electron short of the six d-electrons necessary to reductively cleave the dinitrogen bridge. The necessity of the d⁴ configuration for N2 cleavage is confirmed from calculations on the corresponding NbIII containing d⁴ systems MoIIINbIII and NbIIINbIII which are calculated to have exothermic cleavage steps of 45 and 401 kJ mol⁻¹, respectively. The latter calculations provide a rationale for why [Ar(BuN)₂M(μ-N₂)N₂Pr]Ar, in the presence of the reducing KC₇₇, undergoes spontaneous cleavage of the dinitrogen bridge since the reduction step is presumably centred on the NbII.
